Characterization of lymphocyte subsets as a tool of assessment of histological disease activity pattern in ulcerative colitis

Hayder F. Ghazi* BSc, MSc

Summary:
Background: In Ulcerative colitis (UC), the presence of a persistently elevated number of T cells in the inflamed area with respect to the activity of the disease suggesting bad prognosis. This study was done to evaluate cellular immune response in different disease activity patterns and its possible implication in evaluation of disease activity.

Materials and methods: This study included Forty seven archived paraffin-embedded samples of ulcerative colitis; these samples diagnosed and graded for disease activity. Then dual immunofluorescence staining was used for phenotyping of lymphocytic infiltrate (CD3- CD19) and (CD4-CD8). A total and differential T cell as well as plasma cell count was recorded in these UC tissue samples. Non parametric Kruskal-Wallis test was used to compare the median cell counts among different study groups.

Results: There is higher lymphocytic infiltrate for all types of cells when UC samples compared with control samples with highly statistical significant difference, T cells represents the major constituents of colonic mucosal infiltrate (86.89%) and about 75.79% were CD4 positive T cells. T-cell subsets and plasma cell have high statistical significant difference (p≤0.001) according to histological grade. Furthermore, with the histological grade the highest association found with T lymphocytes (r=0.944) followed by T helper (r=0.821), T cytotoxic (r=0.653) and B lymphocyte (r=0.237).

Conclusions: Qualitative and semi quantitative characterization of lymphocytes subsets was useful in the assessment of different histological grades of UC disease activity.

Keywords: Ulcerative colitis, disease activity and lymphocytes.

Introduction:
Ulcerative colitis (UC) is an inflammatory disease of the rectal and colonic mucosa and seems to result from a complex series of interactions between susceptible genes, the environment and the immune system (1, 2). The total numbers of infiltrating subpopulations of lymphocytes are increased, not normally present in the lamina propria of the intestine (3, 4) indicating ongoing recruitment to the inflamed bowel, bearing in mind their function, lymphocytes may contribute to intestinal damage (5). It appears as though the T-cell response to the antigens is not T-helper (Th) 1 dominant as in the case of Crohn's disease but rather is either Th2 [interleukin (IL)-4, IL-13] or is mediated by specialized cells such as natural killer (NK) T cells (IL-13). Lamina propria T cells from ulcerative colitis patients produce significantly greater amounts of IL-13 (6). The histological examination of routinely processed colonic sections indicates alterations in intensity and composition of the lamina propria infiltrate, which allow a distinction among different disease activity patterns. Over the years, several microscopic scores for the assessment of disease activity in UC have been developed, generally for study purposes (7,8), it could be used to document disease evolution, or to assess clinical efficacy in therapeutic trials and prediction of relapse (9, 10). So, by application of our simple basic immunological knowledge through examination of lymphocytes subpopulations in tissue biopsies by a sensitive and specific assay (dual immunofluorescence cellular staining) could open a way toward proper assessment of in the degree of bowel inflammation. This study was designed to determine the significance and prognostic value of various infiltrating lymphocytes in ulcerative colitis.

Materials and Methods:
Samples Forty seven archived paraffin-embedded blocks of UC patients samples diagnosed at the Gastro Intestinal Tract and Liver Disease Hospital-Baghdad to have ulcerative colitis were included in this study. Patient’s characteristics are presented in Table 1.

Original Article
Lymphocytes subpopulations were identified by two sets of dual staining monoclonal antibodies labeled with Florescen Isothiocyanate (FITC) and Rhodamin Phycocreathin (RPE) as ordered as (anti-CD3, anti-CD19 and anti-CD4, anti-CD8) respectively. Direct dual-Immunofluorescence procedure:

1. Dewaxing and rehydration: paraffin embedded sections were placed inside a hot air oven at 65°C overnight, then dipped in xylene and ethanol containing jars in the following order:
   a. Xylene for 5 minutes.
   b. Fresh xylene for 5 minutes.
   c. Absolute ethanol for 5 minutes.
   d. Ethanol (95%) for 5 minutes.
   e. Ethanol (70%) for 5 minutes.
   f. Ethanol (50%) for 5 minutes.
   g. Distilled water for 5 minutes.
2. For blocking the non-specific binding sites, 100 µl of a protein-blocking reagent was placed onto the section and incubated for 10 minutes in a humid chamber at room temperature. Then slides were drained and blotted gently.
3. 50 µl of diluted primary antibody was placed onto the section and incubated for 1 hour at 37°C in a humid chamber. After incubation, the slides were drained and blotted gently.
4. Slides were dehydrated by dipping in ascending concentration of ethanol and xylene containing jars in the following order:
   h. Ethanol (50%) for 5 minutes.
   i. Ethanol (70%) for 5 minutes.
   j. Ethanol (95%) for 5 minutes.
   k. Absolute ethanol for 5 minutes.
   l. Fresh xylene for 5 minutes.
5. A drop of mounting medium (DPX) was placed onto the xylene-wet section then quickly covered with a cover slip.
6. Slides were examined under fluorescent microscope at X400 magnification.

Statistical analysis:
Data were recorded as median values and non parametric Kruskal-Wallis test for one way ANOVA was used to compare the median cell counts among different study groups and p-value <0.05 was considered significant.

Results:
Lymphocytic constituents in inflamed mucosa compared with control: All cases were investigated for determining CD3/CD19 and CD4/CD8 expression based on dual immunofluorescence staining technique. Total number of T cells and subsequent cellular subsets (CD3+,CD4+, CD8+, and CD19 cells). Nearly 86.89% of the intestinal epithelium of UC patients was CD3 positive. Dual immunofluorescence labeling confirmed that the majority of them were CD4 positive cells (80.82%) and the rest were CD8 positive (19.18%). Other findings showed that the numbers of lymphocytes, both T cells and B cells, are indeed increased in UC patients than those of control biopsies table 1. Our results showed that the mucosa in UC colon tissue was characterized by a 8.5 fold increase in lymphocytes compared with normal colon. For all lymphocytic infiltrates there were highly statistical significant difference between UC patients and control reflecting the inflammatory status of colonic mucosa. According to histological grading, our records were classified and compared in Table-2.

* = statistical significant difference.
** = highly statistical significant difference.

The results showed that there were highly statistical significant differences for all cell types reflecting the constituents of inflammatory cells in the colonic mucosa in relation to the grade of disease activity. This inclination was further explained in figure 1 and correlation coefficient between lymphocyte subsets and histological grade shown in the legend of figure 1. The highest association found with T lymphocytes (r=0.944) followed by T helper (r=0.821), T cytotoxic (r=0.653) and B lymphocyte (r=0.237).
Characterization of lymphocyte subsets as a tool of assessment of histological disease activity pattern in ulcerative colitis

Figure 1: Scatter blot showing the distribution of cellular phenotype in correlation with histological grade.

Figure 2: Dual immunofluorescence (A, B, C and D) staining of ulcerative colitis lesions (X400). Colon stained with Anti (CD3-CD19) antibodies. (A) Stained cells can be seen in aggregates near the muscularis mucousa and extended through lamina properia showing several T-cells (CD3+ve) (1) and fewer plasma cells (CD19+ve) at the crypts base near the muscularis (basal plasmocytosis) (2) (grade III). (B) T-helper (CD4+ve) (3) extensively infiltrated through lamina properia and fewer T- cytotoxic (CD8+ve) transmucosal infiltration seen in this section (4) (grade II). (C) Both T-cells and plasma cell were distributed in the lamina properia, note that plasma cells in the base of mucousa and between crypts (5) (grade II). (D) Extensive random infiltration of both helper-1 and helper-2 cells among destructed crypts (6) (grade VI).

Discussion:
The immunophenotyping of cellular subsets seen in Ulcerative colitis tissue biopsies forms the basis of understanding the cellular immune response in various disease activity patterns. In UC disease there is infiltration of the mucosa with lymphocytes, Both T cells and B cells (11, 12). As shown in this study, however, the proportions of T lymphocyte subsets, as defined by monoclonal antibodies, do not differ, either in the epithelium or in the lamina propria, from those seen in normal colonic mucosa.
This is true both in ulcerative colitis and in Crohn's disease, regardless of disease activity or mode of treatment. These mucosal populations are also similar to those seen in normal small intestine this findings indicate that the pathogenesis of inflammatory bowel disease does not depend upon an imbalance of the immunoregulatory T cells defined by the monoclonal antibodies used in this study. They also suggest that the reduction in the number of circulating T lymphocytes seen in patients with inflammatory bowel disease, without alteration in the proportions of T cell subset (13) may well be because of sequestration into involved mucosa. This emphasises the need to study events in the mucosa rather than those in the peripheral blood. The total number of cells of the inflammatory infiltrate was more than the total number of cells that were stained with dual monoclonal antibodies (immunofluorescence). This indicates that there may be other cells that form part of a chronic inflammatory infiltrate including the fibroblasts, histiocytes, macrophages and dendritic cells (14). The inflammatory cellular infiltrate in active lesions contained a large number of CD3+ cells but a low CD4+ and CD8+ cell count. By comparing the immunophenotype of different disease activity lesions of UC, we were mostly able to confirm the previous reports of other researchers that the bulk of the inflammatory infiltrate is made up of T cells (15, 16, 17). The predominant cells in the inflammatory infiltrate are CD3+ cells and less CD19 B cells, and a small percentage of CD4+, CD8+ cells. Also a large percentage of cells were seen in the infiltrate, which were CD3+, CD4- and CD8-, these were presumed to be gamma delta cells. UC is also characterized by a special distribution of inflammation and architectural distortion with increasing intensity from the proximal towards the distal colon. Regarding T cells, total numbers of T cells are increased in tissue samples (14) while the ratio of CD4+ to CD8+ cells is unchanged in patients with inflammatory bowel disease harbors high numbers of bacteria compared with controls.
