Abstract

The present work includes anatomical, histological and histochemical study of the pancreas in early hatched Goose (Anser anser). The current study was performed on ten early-hatched goose ageing from 5-10 days clinically healthy. The animals were anaesthetized by the ether after which they were carefully dissected and examined. Anatomical study shown pancreas it is a vital lobulated organ, pale pinkish in colour, located on the right side of the abdominal cavity between the descending and ascending duodenal loops closely covered by mesentery pancreatic duodenal ligament and Its consist of dorsal, ventral, third and splenic lobe. Histologically parenchyma of gland consisted of exocrine and endocrine parts was located in the meshwork of reticular fibres. Exocrine part was arranged in form of serous tubuloacinar glands that occupied a larger area of pancreas. The islands of langerhans consisted of various shapes and sizes of alpha, beta cell and mixed islets were not observed in the early hatched goose pancreas.

Introduction

Goose are waterfowl birds belonging to the tribe Anserini of the family Anatidea (1). These species of birds are from within important domestic birds which featuring by high resistance disease when it breeding in different environmental conditions and also considered friends of farmers compare with the other type of the birds because hight fatty liver production in the world (2, 3), and play important role for the controlling the harmful pests of crops (4).

Accessory organs of digestive system includes (liver and pancreases), the pancreas of birds is the largest accessory gland connected with alimentary tract; it is consist of exocrine and endocrine compartments (5, 6).The exocrine part secretion of many essential enzymes and many electrolytes released in digestive system (7, 8).While the endocrine part of pancreas consist of large and small islets (Langerhans islets) (9). The islets are named as alpha, beta and mixed islets according to their cellular composition, these islets responsible for released regulated hormone like insulins into blood vessels (10, 11, 12). Many differences in the structure, location, distribution of the islets and
structure of ducts between pancreases of birds and other species of animals (13). The present study was conducted to investigate the structure of pancreases in early hatched goose (Anser anser) to provide baseline information.

**Material and Methods**

**The Experimental Animals**

The experiment was conducted on ten early hatched goose, age ranging from 5-10 days. They were immediately transferred to the veterinary anatomy laboratory in Al-Qadisiyyah University. The animals were anaesthetized by ether after which they were carefully dissected through a mid-ventral incision from the inguinal region to the mandibular symphysis. Anatomical studies were conducted, including the measurement of weight, length, and thickness of pancreas lobes and recorded. Specimens for histological study were collected immediately after gross examination. The specimens were fixed in 10% formalin for about 24 hours. The samples were then dehydrated in a graded series of alcohol, cleared in xylene, and embedded in paraffin wax. Sections of 4–6 μ thickness were mounted on clean glass slides and stained with haematoxylin and eosin (H&E) for general structure and PAS stains to study the histochemical features of the pancreases (14, 15).

**Results**

**Gross study**

The anatomical studies that appear in this study indicate that the pancreas of early hatched goose is a lobulated organ, pale pinkish in color, located on the right side of the abdominal cavity between the descending and ascending duodenal loops. The mean weight of the pancreas is (3.721±0.06) g. The mean weights of the dorsal, ventral, splenic, and third lobes are (2.085±0.02), (1.576±0.02), (0.033±0.01), (0.027±0.02) g respectively. The mean length of the dorsal lobe is (2.33±0.05) cm, the ventral lobe is (2.388±0.03) cm, splenic lobe (1.13±0.03) cm, and third lobe (1.02±0.02) cm, respectively.

Histological study shows the pancreas was covered by a thin connective tissue capsule, which consists of collagenous, elastic, and reticular fibers and was lined by mesothelium. Extending from the capsule, septa divide the gland into lobules (Fig. 4). Blood, lymph vessels, nerves, and excretory ducts run within the connective tissue septa. The parenchyma of the gland consists of exocrine and endocrine parts. The exocrine part is arranged in the form of serous tubuloacinar glands that occupy a larger area of the pancreas and these tubuloacinar glands consist mainly of mutable number of acinar cells which take the form of pyramidal or tall columnar in shape having basophilic base and many apical acidophilic granules (Fig. 6). Some of centro acinar cells without granules were observed in the lumen of the acinus as the beginning cells of the intercalated ducts.

Langerhans islet is composed of different shapes and sizes of alpha and beta cells, either mixed cells do not notice in the pancreas of early hatching geese. Alpha islets bigger than beta does not have a distinctive border with the exocrine part while the beta islets...
were arising from surrounding secretory acini by delicate collagenous fibers; also, there were few fibers within islets tissue (Fig. 7).

Intercalated ducts and interlobular ducts lined by thin layer of simple to stratified columnar epithelium and surrounded by connective tissue. In addition to this, the smooth muscle surrounding both the main pancreatic duct and interlobular ducts. Externally to these smooth muscle fibers, there were connective tissues of the tunica adventitia.

(Table 1) showed the pographic measurements including weight and length of pancreas lobes, n=10, M± SE)

Discussion
The anatomical studies demonstrates pancreas of early hatched goose it is a vital lobulated organ consist of four lobes located between the descending and the ascending duodenal loops and not full the space between the two limbs of duodenum, this finding is in agreement with the result of (16), (17) and (18) but disagreement with the (19), who said that the lobes of pancreas were very short and have a gap between the duodenal limbs, also disagreement with the (20) who reported the pancreas of ducks has two lobes and the dorsal lobe is divided into three distinct segments.

The histological study observed exocrine part consist of tubuloacinar glands that occupied larger area from the parenchyma of pancreas; the present observations are consistence with those observations of (19), (21) and (22) we are found that the exocrine portion was composed of acini and ducts.

Also histological study demonstrate the islands of langerhans consisted of alpha or beta cell while mixed islets were not observed; these data disagreement with results of (23) and (24) were demonstrated islands of langerhans containing alpha, beta and delta cells.

The result of this study showed the main excretory ducts were lined by simple to stratified columnar epithelium, this result agreed with the (21) in duck. These ducts have inner longitudinal and outer circular muscle layers surrounded by the externally connective tissue and nerve fibers enter the parenchyma of glands along connective tissues, this results enhanced with (25) in duck.
