Abstract: The present study was designed to find out the usefulness of lactate dehydrogenase (LDH) level in cerebrospinal fluid (CSF) in differentiating bacterial from non-bacterial meningitis in children below 5 year of age. A total of 177 patients who were admitted to the AL-Ramadi Maternity and children hospital, AL-Anbar, Iraq during a period of one year (from 1st November 2007 to 1st November 2008), for diagnosis and treatment of meningitis were included in the study. Cerebrospinal fluid samples were collected from patients by lumbar puncture (LP) for diagnosis. Levels of LDH were measured spectrophotometrically in Randox commercially prepared kits and compared in bacterial, non-bacterial meningitis and controls. The study revealed that only 24 cases have meningitis. Bacterial meningitis present in 19 (79%) of them 11 (46%) with positive culture and 8 (33%) with negative culture (partially treated), while the remaining 5 (21%) were found to be non-bacterial cases. The study concluded that measurement of LDH levels in CSF is beneficial in differentiating bacterial from non-bacterial meningitis since it was significantly increased in bacterial meningitis.

Key words: Lactate Dehydrogenase, Meningitis, Ramadi

Introduction:

Meningitis is an inflammation of the arachnoid, pia mater, and the intervening cerebrospinal fluid. It can be caused by variety of infectious agents, bacterial meningitis is a significant cause of morbidity and mortality, especially in pediatric population. Meningitis also can caused by viral, fungi, chemical irritation, drug allergies and tumors. Lactate dehydrogenase, a tetramer protein comprised of four monomer, is expressed as five isoenzymes having different distribution in various tissues. Brain tissue which is dependent in aerobic metabolism has a predominance of the aerobically active LDH1 and LDH2 isoenzymes. Lactate dehydrogenase is intracellular enzyme, it is sensitive indicator of bacterial meningitis. Lactate dehydrogenase is intracellular enzyme, it is sensitive indicator of bacterial meningitis. Lactate dehydrogenase is intracellular enzyme, it is sensitive indicator of bacterial meningitis.

The main objective of the present study was to estimate lactate dehydrogenase levels in CSF sample from patients under 5 years age with meningitis and evaluate the benefit of this important enzyme in differential diagnosis of meningitis.

Experimental:

A prospective hospital based study was done during a period of one year (from 1st November 2007 to 1st November 2008). All patients from one month to 5 years admitted to the AL-Ramadi maternity and children hospital in Al-anbar governorate, Iraq with a
presumptive diagnosis of meningitis were included in the study.  

2-5 ml of CSF which had been collected by L.P were sent directly to the hospital laboratory to be studied for cell count and differential, protein, sugar, lactate dehydrogenase level, gram stain, and culture.  

The level of LDH was considered as high when it is more than 22 U/l 15. Levels of LDH in CSF were estimated using a colorimetric method in a commercially prepared kits produced by Randox UK company.  

Data were analyzed statistically using SPSS version 10. P value less than 0.05 was considered significant. Validity of the test was calculated according to its sensitivity, specificity, positive predictive value, negative predictive value, and accuracy.  

**Results**  

A total of 24 cases were regarded as meningitis with CSF cells more than 5. Cerebrospinal fluid culture for meningitis were positive in 11 (46%), while 8 (33%) cases had negative results which considered as partially treated and the remaining 5 (21%) regarded as non bacterial meningitis. Eight patients (33.3%) of meningitis cases were received antibiotic before admission to the hospital. Twenty four samples that were found to be clear (non meningitic) were used as controls.  

Patients were grouped according to age into three groups (1month to 1year, 1 year to 3 years, and 3-5 years). The highest number and percentage of meningitis patients were noticed in first age group (1 month to 1 year) which represent 11 (45.8%), followed by the second age group 10 (41.7%), while only 3 patients of cases were recorded in the third age group (Table 1).

Comparison between bacterial and non bacterial and bacterial and controls was significant ( P value =0.001).while comparison between non bacterial and controls was not significant ( P value >0.05)
are supported by many reports 31, 32, 33, 34, however, high index of suspension of meningitis and rapid diagnosis is essential for favorable results, thus the test under study is easy and rapid and can be done rotenly in all hospital laboratories and it will prevent the delay in diagnosis which may increase morbidity and mortality due to this important disease.

In the present study, the usefulness of CSF-LDH is in differentiating between bacterial and non-bacterial meningitis (P. value < 0.05) is comparable with other researches 35,36,37. However, some investigators reported that LDH-CSF may not be useful in differentiation between septic and aseptic meningitis but it may act as a corroborative evidence of meningitis. 38,39,40, however, it is a rapid, relatively sensitive, specific, and easily performed test and helpful in differentiating bacterial from non-bacterial meningitis. It is recommended to be used in the laboratory procedures beside conventional methods. Further future studies are recommended on the analysis of LDH isoenzymes pattern in CSF and serum to determine the benefit of LDH sub fractions (LDH1, LDH2, LDH3, LDH4, LDH5) in differential diagnosis of meningitis.

Depending a cutoff point of 22 IU/L, the % sensitivity, % specificity, % Positive Predictive Value, % Negative Predictive Value, and % Accuracy of the test were found to be 89.4, 80, 94.4, 66.6, and 87.5 respectively.

Discussion:
Meningitis is still a very common and serious disease that may lead to death and many of those who survive may be left disabled. The final outcome depends on considerable degree of early diagnosis and appropriate treatment.

The routine examination of CSF for cell count, glucose, and protein when meningitis is suspected, along with use of gram’s stain and bacterial culture, are all valuable in differential diagnosis of meningitis 13.

The present study included 177 CSF samples from patient admitted to the maternity and childhood hospital in Ramadi city with a presumptive clinical diagnosis of meningitis. Of them 24 patients were proved to be meningitis cases. 19(79%) of them have bacterial meningitis 11(46%) with positive culture and 8(33%) with negative culture (partially treated), while the remaining 5(21%) were found to be non-bacterial cases, similar results were reported as bacterial meningitis and non-bacterial meningitis in Saudi (68.32%), Oman(37%), and Libya(74%).

Thirty three percent of meningitis cases had received antibiotics before admission to hospital which is the probable cause to give negative CSF culture. Similar observations were reported in United State of America (10%)17, United Kingdom (18%)18, and Iraq (14.3)%.

In the present study, the highest number of patient with meningitis was noticed in the first age group (1month_1 year) (45.8%), which was more than other age groups but the difference was statically not significant (P. value > 0.05), these findings are in agreement with many reports from Palestine (46.6%), Oman(48.2%), and Libya(49.4%).

The incidence of bacterial meningitis is higher in developing countries than developed countries and particularly high in children under one year of age. 23,24,25,26 The possible causes are immaturity of the immune system, and the lack in the pre – exposure of the body to these organisms, which enhance the memory of the immune system to fight against these invaders.

According to sex, we found that males were more affected than females in ratio 1.66:1, but the difference was statically not significant (P. value > 0.05), similar results were reported by some investigator 29, 30. The little predominance of male patient in meningitis could be attributed to many factors e.g. the outside home contacts which is more in males than females, and the exposure of males to many factors from community like active or passive exposure to cigarette smoking.

The % sensitivity, % specificity, % Positive Predictive Value, % Negative Predictive Value, and % Accuracy of the test were found to be 89.4, 80, 94.4, 66.6, and 87.5 respectively. These findings

الخلاصة

صممت الدراسة الحالية بهدف عرفة أهمية تركيز إنزيم اللاكتوتين ديهيدروجيناز في السائل المخي الشوكي في التفريق بين التهاب السحايا الجنوبي وغير الجنوبي في الأطفال تحت سن الخامسة من العمر بعنوان من أعراض وعلامات التهاب السحايا والتدخل المستفيشي لعقار التشخيص والعلاج للمرة من 1 تشرين الثاني 2007 إلى 1 تشرين الثاني 2008 حيث تم جمع السائل المخي الشوكي من هؤلاء الأطفال بطريقة الزناد القطني لعقار التشخيص كما تم قياس تركيز إنزيم اللاكتوتين ديهيدروجيناز بطرق المطياف الضوئي من خلال الطرق المخبرية المتعددة للتشخيص تبين أن 24 حالة بفاعلا من التهاب السحايا. حيث النتائج أن 19 حالة (79%) يعانون من التهاب السحايا البكتيري ويتسمون إلى حالة 11 حالة (46%) كانت نتيجة الزرع البكتيري موجبة وأن 8 حالات (33%) كانت نتيجة الزرع البكتيري سلبية بينما عد العدد المتبقي 5 حالات (21%) هو التهاب سحايا غير بكتيري. استنتجت الدراسة أن بالإمكان الاستفادة من قياس تركيز إنزيم اللاكتوتين ديهيدروجيناز في السائل المخي الشوكي للتفريق بين نوع التهاب السحايا إذا وقع في حالة التهاب السحايا البكتيري.
