Abstract
The present study aims to detecting several biochemical markers and cytokines in obese and normal lean Iraqi women. Forty women (♀ obese and ♂ lean) were chosen from different areas in Baghdad city there ages ranges between 22-26 years and body mass index (BMI) between 32.3 ± 8.2 Kg/m². The study showed a high significant increment in Fasting Blood Glucose (FBG), serum cholesterol and Homeostasis Model Assessment (HOMA) in obese women as compared with lean and a significant increment in HDL (High Density Lipoprotein) in lean women when compared with obese ones. A significant correlation coefficient (r) was noticed between BMI and studied parameters, FBG, cholesterol, triglyceride, insulin, HOMA, high sensitive C Reactive Protein (hs-CRP), Tumor Necrosis Factor alfa (TNF-α) and IL-1².

Keywords: Obesity. BMI, Cholesterol, Inflammatory Mediator.

Introduction
Obesity is a medical condition in which excess body fat has accumulated to the extent that it may have an adverse effect on health, leading to reduced life expectancy and/or increased health problems [1,2]. Obesity increases the likelihood of various diseases, particularly heart disease, type ♂ diabetes, obstructive sleep apnea, certain types of cancer, osteoarthritis [2] and asthma [2]. It is most commonly caused by a combination of excessive food energy intake, lack of physical activity, and genetic susceptibility, although a few cases are caused primarily by genes. Obesity is defined by body mass index (BMI) and further evaluated in terms of fat distribution via the waist–hip ratio and total cardiovascular risk factor [3,4]. BMI is closely related to both percentage body fat and total body fat [3]. As a result, obesity has been found to reduce life expectancy [3]. At an individual level, a combination of excessive food energy intake and a lack of physical activity is thought to explain most cases of obesity [3]. A limited number of cases are due primarily to genetics, medical reasons, or psychiatric illness [3]. In contrast, increasing rates of obesity at a societal level are felt to be due to an easily accessible and palatable diet [3] increased reliance on cars, and mechanized manufacturing [1,4]. Obesity is one of the leading preventable causes of death worldwide [5-7]. American and European studies have found that mortality risk is lowest at a BMI of 22.0-29.0 kg/m² in non-smokers [4,7] and at 24.0-27.0 kg/m² in current smokers, with risk increasing along with changes in either direction [1,8-10]. A BMI above 30 kg/m² has been associated with a doubled mortality rate among women over a 17-year period [11]. In the United States obesity is estimated to cause 111,000 to 325,000 deaths per year [12], while 1 million (4,2) of deaths in Europe are attributed to excess weight [13]. On average, obesity reduces life expectancy by six to seven years [14,15]. BMI of 25.0-30.0 kg/m² reduces life expectancy by two to four years [16], while severe obesity (BMI > 40 kg/m²) reduces life expectancy by ten years [17]. Complications are either directly caused by obesity or indirectly related through mechanisms sharing a common cause such as a poor diet or a sedentary lifestyle. The strength of the link between obesity and specific conditions varies. One of the strongest is the link with type ♂ diabetes. Excess body fat underlies 74% of cases of diabetes in men and 77% of cases in women [18]. Health consequences fall into two broad categories: those attributable to the effects of increased fat mass (such as osteoarthritis, obstructive sleep

173
apnea, social stigmatisation) and those due to the increased number of fat cells (diabetes, cancer, cardiovascular disease, non-alcoholic fatty liver disease) [1,2,3]. Increases in body fat alter the body’s response to insulin, potentially leading to insulin resistance. Increased fat also creates a proinflammatory state [4,5,6,7] and a prothrombotic state[9,11,12]. This study aimed to matured some inflammatory and Biochemical parameter and compared results between lean and obese women.

Experimental Work

Patients

The study groups included forty women ♂, obese and ♂, lean control. Women were chosen randomly according to their weight, their ages ranged ♂-♀ years. The controls were selected among subjects who were healthy in terms of regular cycle, normal hormonal assay, non-diabetic, non-hypertensive, no other endocrine disorders and were free of acute illness or infection at time of sampling. In all cases, body weight and height, BMI were measured by using standard methods. All cases were investigated for the Serum levels of insulin, cytokines (IL-α and TNF-α), high sensitive C-Reactive protein in addition to plasma level of glucose and Lipid profile. From each cases ♂ ml of blood were obtained by venepuncture, using a ♂ ml disposable syringe between 6,7,10 and 11,12,13 A.M. The blood sample was divided into two aliquots; ♂ and ♂ ml. The first aliquot was used for the estimation of plasma glucose and lipid profile. The second aliquot was dispensed in a plain tube and left for an hour to clot at room temperature 22°C, and then centrifuged at 3000 rpm for 10 minutes to collect serum. The serum was divided into aliquots (♀-♂ μl) in Eppendorff tubes and stored in the freezer at -20°C until use.

Measurements of Markers

- Serum TNF-α concentration was determined by the sandwich ELISA method (Phoenix Pharmaceuticals, INC, USA).
- Serum IL-α concentration was determined by the competitive ELISA method (Raybiotech Company, USA).
- Serum hs-CRP concentration was determined by the competitive ELISA method (Demedetec Company, Germany).
- Serum insulin concentration was determined by the sandwich ELISA method Serum (Demedetec Company, Germany).
- Cholesterol level was measured by enzymatic end point method supplied by (Bio Labo Company, Franc).
- Triglyceride was determined after enzymatic hydrolysis with lipase into fatty acids and glycerol. The resultant glycerol is then phosphorelatedin the presence of ATP and glycerokinase to give hydrogen peroxide that react in presence of peroxidase with α-aminoantipyrine and parachlorophenol to give colored chromophen equinoneimie (Bio Labo Company, Franc).
- Low-density lipoprotein-cholesterol was estimated by using formula of Friedwald [14].

\[
LDL\text{- cholesterol} = \text{Total cholesterol} - [\text{HDL-cholesterol} + \text{TG/5}]
\]

- Very low-density lipoprotein- cholesterol was estimated by using formula of Friedwald [14].

\[
\text{VLDL-Cholesterol} = \text{TG/6}
\]

- Insulin resistance (IR) was determined by a number of different methods including fasting insulin, glucose for calculation (insulin measured μU/ml, glucose measured in mg/dl), the homeostasis model assessment (HOMA). The estimation of insulin resistance by HOMA score was calculated using Matthews formula [18].

\[
\text{HOMA} = \frac{[\text{Fasting serum insulin (μU/ml)} \times \text{Fasting blood glucose (mmol/L))]}{22}\]

Statistical Analysis

Results were analysed using Statistical Analysis System- SAS (♀♂) T-test was used to significant compared between means. Correlation coefficient was estimated.
Results and Discussion

In the present study, groups were divided in two dependent on BMI obese and lean to note the effect of obesity on the studied factors.

The mean serum level of Tumor Necrosis Factor-α (TNF-α) was non significantly elevation between lean (γ,γ±±,λμg/ml) and obese once (γ,γ±±,λμg/ml), in serum Interleukin-6 (IL-6) the mean values (γ,γ±±,λμg/ml) for lean and (γ,γ±±,λμg/ml) for obese found to be non-significantly elevated, it was also for Serum High sensitive C-Reactive Protein (hs-CRP) found to be non-significantly elevated in obese (γ,γ±±,λμg/ml) with a mean of (γ,γ±±,λμg/L) in lean women, Fasting serum insulin showed non-significant results between lean (γ,γ±±,λμg/ml) and obese once (γ,γ±±,λμg/ml), in Triglyceride there was no significant in lean women (γ,γ±±,λμg/ml) and obese once (γ,γ±±,λμg/ml), in High Density Lipoprotein (HDL) there was a significant increase in lean women (γ,γ±±,λμg/ml) when compared with obese once (γ,γ±±,λμg/ml), in Very Low Density Lipoprotein (VLDL) between lean women (γ,γ±±,λμg/ml) when it compared with obese once (γ,γ±±,λμg/ml), there was a significant increments in serum cholesterol in obese women (γ,γ±±,λμg/ml) when it compared with lean once (γ,γ±±,λμg/ml), also there was a significant increments in Fasting Blood Glucose (FBG) in obese women (γ,γ±±,λμg/ml) when it compared with lean once, and there was a significant increase in Homeostasis Model Assessment (HOMA) in obese women (γ,γ±±,λμg/ml) when it compared with lean once.

Correlation coefficient (r) between BMI and studied parameters

A significant correlation was found between BMI among FBG, Cholesterol, Triglyceride, HOMA, insulin, hs-CRP, TNF-α, IL-6 as shown in Table (1).

The concentration of HDL-cholesterol is adversely altered in obesity, with HDL-cholesterol levels associated with both the degree and distribution of obesity. More specifically, intra - Abdominal visceral fat deposition is an important negative correlate of HDL-cholesterol. The specific subfractions of HDL that are altered in obese states include the HDLγ, apolipoprotein A-I, and pre-beta1 subfractions. Decreased HDL levels in obesity have been attributed to both an enhancement in the uptake of HDL by adipocytes and an increase in the catabolism of apolipoprotein A-I on HDL particles. In addition, there is a decrease in the conversion of the pre-beta1 subfraction, the initial acceptor of cholesterol from peripheral cells, to pre-betaγ particles [γ]. Obesity is at epidemic levels in all age groups. The effect of obesity on cholesterol levels is complex. Overweight individuals
tend to have high triglyceride and LDL levels and low HDL levels. This combination is a risk factor for heart disease. Obesity also causes other effects (high blood pressure, increase in inflammation) that pose major risks to the heart. Darvall and his research team reported that increased levels of both triglycerides and free fatty acids are associated with obesity and insulin resistance [77].

Obesity is particularly dangerous when it is one of the components of the metabolic syndrome, formerly known as syndrome X. This syndrome consists of obesity marked by abdominal fat, unhealthy cholesterol levels, high blood pressure, and insulin resistance. Metabolic syndrome is a pre-diabetic condition that is significantly associated with heart disease and higher mortality rates from all causes. Many doctors recommend that patients with metabolic syndrome should be aggressively treated with high-dose statin therapy to lower LDL levels. Obesity is also strongly associated with type 2 diabetes, which itself poses a significant risk for high cholesterol levels and heart disease [78].

A higher BMI is associated with higher homeostasis model assessment values for insulin resistance (HOMA-IR), homeostasis model assessment of β-cell function (HOMA-β), and insulinyogenic index as well as lower levels of insulin sensitivity index composite (ISIcomp) and disposition index (DI) [79].

These changes are consistent with the lipid profile that is typically found in association with insulin resistance. The effects of insulin resistance on lipid metabolism are well known. Increased secretion of very low-density lipoprotein (VLDL) particles by the liver results in elevated plasma TG concentrations. Subsequently, TGs are exchanged for cholesteryl ester (CE) by the activity of CE transfer protein. This process results in TG-enriched high-density lipoprotein (HDL) particles that are catabolized more rapidly, and CE-enriched VLDL particles that are converted into small dense low-density lipoprotein (LDL) particles [77]. As a consequence, insulin resistance contributes to decreased plasma levels of HDL-C and apolipoprotein (apo) A-I, and higher levels of apo B [77].

The HOMA is a method for assessing β-cell function and IR from fasting glucose and insulin or C-peptide concentrations. The relationship between glucose and insulin in the basal state reflects the balance between hepatic glucose output and insulin secretion, which is maintained by a feedback loop between the liver and β-cells [80]. Decreases in β-cell function were modeled by changing the β-cell response to plasma glucose concentrations. Insulin sensitivity was modeled by proportionately decreasing the effect of plasma insulin concentrations at both the liver and the periphery [81]. Some investigators had recommended calculating an index of IR from glucose and insulin levels (e.g. HOMA) [82]. In previous study HOMA was considered as valid method to assess insulin sensitivity in epidemiological studies [83].

Cytokines such as TNF-α influence several metabolic activities, including glucose and lipid metabolism [84]. Since obesity and IR are frequent findings in hyper androgenic women in the current study, TNF-α concentration were positively correlated with BMI, as shown in table 6. Previous studies have shown the relationship between BMI and TNF-α level [85,86].

The secretion of IL-1β is regulated by several physiologic or pathologic factors: hormones, cytokines, diet, physical activity, stress, hypoxia, and others. Adipose tissue-derived IL-1β may have an effect on metabolism through several mechanisms, including adipose tissue-specific gene expression, triglyceride release, lipoprotein lipase down regulation, insulin sensitivity, and so on [87,88].

IL-1β is believed to be beneficial for insulin-regulated glucose metabolism in muscle. Furthermore, the effects of the cytokine are seemingly influenced by whether it is present acutely or chronically; the latter is the setting associated with insulin resistance [89].

**Conclusion**

In the present study, there was a significant increment in Fasting Blood Glucose (FBG), serum cholesterol and Homeostasis Model Assessment (HOMA) in obese women as compared with lean once
and a significant increment in HDL (High Density Lipoprotein) in lean women when compared with obese once. A significant correlation coefficient (r) was noticed between BMI and studied parameters, FBG, cholesterol, triglyceride, insulin, HOMA, high sensitive C Reactive Protein (hs-CRP), Tumor Necrosis Factor alfa (TNF-α) and IL-α.
